Objective: Respiratory failure represents a significant source of morbidity and mortality for surgical patients. High-frequency percussive ventilation (HFPV) is emerging as a potentially effective rescue therapy in patients failing conventional mechanical ventilation (CMV). Use of HFPV is often limited by concerns for potential effects on hemodynamics, which is particularly tenuous in patients immediately after cardiac surgery. In this manuscript we evaluated the effects of HFPV on gas exchange and cardiac hemodynamics in the immediate postoperative period after cardiac surgery, in comparison with CMV.

Methods: Twenty-four consecutive cardiac surgery patients were ventilated in immediate postoperative period with HFPV for two to four hours, then they switched to a CMV using the adaptive support ventilation mode for weaning. Arterial blood gases were performed during the first and second hour on HFPV, and at 45 minutes after initiation of CMV. Respiratory settings and invasive hemodynamic data (mixed venous oxygen saturation, central venous pressure, systemic and pulmonary blood pressure, cardiac output and index) were collected utilizing right heart pulmonary catheter and arterial lines during HFPV and CMV. Primary outcome was improvement in the ratio between partial pressure of oxygen to fraction of inspired oxygen (P/F ratio) and changes in hemodynamics.

Results: Analysis of data for 24 patients revealed a significantly better P/F ratio during the first and second hour on HFPV, compared with a P/F ratio on CMV (420.0 ± 158.8, 459.2 ± 138.5, and 260.2 ± 98.5 respectively, p < 0.05), suggesting much better gas exchange on HFPV than on CMV. Hemodynamics were not affected by the mode of the ventilation.

Conclusions: Improvement in gas exchange, reflected in a significantly improved P/F ratio, wasn’t accompanied by worsening in hemodynamic parameters. The significant gains in the P/F ratio were lost when patients were switched to conventional ventilation. This data suggest that HFPV provides significantly better gas exchange compared with CMV and can be safely utilized in postoperative cardiac patients without any significant effect on hemodynamics.

INTRODUCTION

Postoperative respiratory failure is a significant source of morbidity and mortality in postoperative patients. Postoperative pulmonary alterations after cardiac surgery include increased minute ventilation, breathing frequency, CO2 production and oxygen consumption, and decreased tidal volume [1]. Postoperative pulmonary complications in open-heart surgery also have an effect on gas exchange making it difficult to manage postoperative patients while on the mechanical ventilator and after extubation. Intrapulmonary shunting has been shown to be a large component of impaired gas exchange before, during, and after cardiac surgery [2]. Recruitment of lung tissue with increased lung volume may be beneficial in reducing intrapulmonary shunting and the resultant hypoxemia [3]. The methods employed for lung recruitment are widely varied, and there is considerable variance among methods in clinicians treating this patient population. Some of the recruitment maneuvers include high positive end expiratory pressure (PEEP), prone positioning, inhaled...
The use of high-frequency percussive ventilation

vasodilators, high-frequency oscillatory ventilation, and high-frequency percussive ventilation (HFPV) [4]. Although, these maneuvers can be effective, they are not without significant practical difficulties when utilized in postoperative cardiac surgery patients. The often-fragile hemodynamic status of postoperative cardiac surgery patients requiring vasopressors and inotropes would benefit from methods that maximize lung recruitment and improve gas exchange without hemodynamic embarrassment. In this manuscript we compare gas exchange with hemodynamic performance of conventional mechanical ventilation (CMV) and HFPV.

HFPV was delivered via volumetric diffusive respirator (VDR-4; Percussionaire Corporation, Sandpoint Idaho USA). The VDR is classified as a pneumatically driven, time-cycled, high-frequency flow interrupter, intermittent mandatory ventilation [5]. It uses a sliding venturi to inject sub-tidal volumes at high frequencies. Settings include pulsatile flow rate, oscillatory continuous positive airway pressure (CPAP), PEEP, inspiratory time, expiratory time, pulse frequency, and pulse inspiratory and expiratory (I:E) ratio. The sliding venturi precisely stacks the injected sub tidal volumes at the high-frequency rate set, for the inspiratory time selected. The inspiratory time is time cycled off, allowing a drop to oscillatory CPAP/PEEP for the selected expiratory time. High-frequency rates may be varied from 80 to 1000 cycles per minute with the VDR-4.

HFPV has been used to improve gas exchange in patients with adult respiratory distress syndrome (ARDS) failing conventional ventilation, while increasing mean airway pressure and decreasing peak airway pressure without affecting hemodynamics [6, 7]. Previous studies have shown HFPV to be effective in reducing intracranial pressure in traumatic brain injury [8, 9], treating lung injury associated with burns and inhalational injury [10–13], recruiting lung volume and improving hypoxemia in pulmonary resection [16], and improving oxygenation and providing lung protective ventilation in pediatric acute respiratory failure [17]. HFPV was also used as salvage therapy in patients after cardiac surgery [18] and in morbidly obese patients [19]. To date, there have been no studies demonstrating improvement in oxygenation in the immediate postoperative period in cardiac surgery patients and its effects on hemodynamics.

METHODS

This study was approved by the New York Methodist Hospital Institutional Review Board for scientific and ethical merit. Twenty-four consecutive cardiac surgery patients undergoing elective cardiac surgery were recruited from February 2012 to April 2012. After arrival from the operating room the patients were transferred from the conventional ventilator used in the operating room to HFPV mode. HFPV mode was utilized for ventilation until initial hemodynamic and respiratory stability was achieved, followed by transitioning to CMV in two to four hours. Hemodynamic and respiratory stability was defined as stable vital signs, pressor, and inotrope requirements and stable acid base status of the patient.

Basic initial VDR settings include high-frequency rate of 500–600 percussions per minute, convective rate of 12 to 16 breaths per minute, oscillatory CPAP of 5 cm H$_2$O, the lowest pulsatile flow rate leading to the rise of the chest, fraction of inspired oxygen (FiO$_2$) of 70%, and I:E ratio of 1:1 on both convective and percussive rate (Figure 1). Humidification was provided by humidifier (MR 850, Fisher & Paykel, Auckland, New Zealand) set up at 37° C. Arterial blood gases (ABGs) were recorded at 15–30 minutes during the first and second hour HFPV, and 45 minutes after transition to CMV from HFPV. When hemodynamic and respiratory stability was achieved after two to four hours of HFPV, the patients were transferred to CMV for weaning and extubation (Hamilton G5, Hamilton Medical AG, Bonaduz, Switzerland). The mode used on the Hamilton G5 for weaning and extubation was adaptive support ventilation (ASV), which is classified as pressure-controlled intermittent mandatory ventilation.

ASV is a closed-loop mode of ventilation that provides ventilatory support based on the patient’s work of breathing. ASV uses Otis’ equation to predict a tidal volume and respiratory rate that minimizes the patient’s work of breathing [20]. The operator enters the patient height, gender, and percent minute volume (%MV), PEEP, FiO$_2$.

The use of high-frequency percussive ventilation

CONCLUSIONS

In this population of postoperative open-heart cardiac surgery patients, HFPV was able to significantly improve gas exchange as reflected by a better P/F ratio without hemodynamic consequence.
